We employ two simple and robust results to constrain the mixing matrix of the isosinglet scalar mesons $f_0(1710)$, $f_0(1500)$, $f_0(1370)$: one is the approximate SU(3) symmetry empirically observed in the scalar sector above 1 GeV and confirmed by lattice QCD, and the other is the scalar glueball mass at 1710 MeV in the quenched approximation. In the SU(3) symmetry limit, $f_0(1500)$ becomes a pure SU(3) octet and is degenerate with $a_0(1450)$, while $f_0(1370)$ is mainly an SU(3) singlet with a slight mixing with the scalar glueball which is the primary component of $f_0(1710)$. These features remain essentially unchanged even when SU(3) breaking is taken into account. The observed enhancement of $\omega f_0(1710)$ production over $\phi f_0(1710)$ in hadronic J/ψ decays and the copious $f_0(1710)$ production in radiative J/ψ decays lend further support to the prominent glueball nature of $f_0(1710)$. We deduce the mass of the pseudoscalar glueball G from an η - η' - G mixing formalism based on the anomalous Ward identity for transition matrix elements. With the inputs from the recent KLOE experiment, we find a solution for the pseudoscalar glueball mass around (1.4 ± 0.1) GeV, which is fairly insensitive to a range of inputs with or without Okubo-Zweig-Iizuka-rule violating effects. This affirms that $\eta(1405)$, having a large production rate in the radiative J/ψ decay and not seen in $\gamma\gamma$ reactions, is indeed a leading candidate for the pseudoscalar glueball. It is much lower than the results from quenched lattice QCD (> 2.0 GeV) due to the dynamic fermion effect. It is thus urgent to have a full QCD lattice calculation of pseudoscalar glueball masses.

1. Introduction

The existence of glueballs is an archetypal prediction of QCD as a confining theory. Despite a great deal of experimental and theoretical efforts in the last 3 decades, there is still no any compelling evidence for their existence. Surely, there are good glueball candidates, such as $f_0(1710)$ and $\eta(1405)$ which are seen copiously in J/ψ radiative decays and yet not observed in $\gamma\gamma$ reactions.¹ However, definitive identification has been plagued by the complication that the branching ratios of these candidates in the radiative decay of J/ψ , once thought to be the defining channel to probe the glue-rich content of the mesons, are not orders of magnitude large than the other known $q\bar{q}$ mesons, that the glueball can mix with ordinary mesons, and the fact that the statistics in experiments are neither high enough to confidently detect all the major decay channels nor precise enough to disentangle from the near-by states such as $f_0(1790)$ and $\eta(1475)$. In this case, the supplemental information on the quark content (or rather the lack of) via the $\gamma\gamma$ coupling and

leptonic decays prove to be important to reveal the nature of the glueball candidates.

2. Scalar glueball

It is generally believed that the scalar glueball is hidden itself somewhere in the isosinglet scalar mesons with masses above 1 GeV. The argument goes as follows. Many scalar mesons with masses lower than 2 GeV have been observed and they can be classified into two nonets: one nonet with mass below or close to 1 GeV, such as σ , κ , $f_0(980)$ and $a_0(980)$ that are generally believed to be composed of four quarks and the other nonet with mass above 1 GeV such as $K_0^*(1430)$, $a_0(1450)$ and two isosinglet scalar mesons. This means that not all three isosinglet scalars $f_0(1710)$, $f_0(1500)$, $f_0(1370)$ can be accommodated in the $q\bar{q}$ nonet picture. One of them should be primarily a scalar glueball.

Among the isosinglet scalar mesons $f_0(1710)$, $f_0(1500)$ and $f_0(1370)$, it has been quite controversial as to which of these is the dominant scalar glueball. It has been suggested that $f_0(1500)$ is primarily a scalar glueball,² due partly to the fact that $f_0(1500)$, discovered in $p\bar{p}$ annihilation at LEAR, has decays to $\eta\eta$ and $\eta\eta'$ which are relatively large compared to that of $\pi\pi$ ³ and that the earlier quenched lattice calculations⁴ predict the scalar glueball mass to be around 1550 MeV. Furthermore, because of the small production of $\pi\pi$ in $f_0(1710)$ decay compared to that of $K\bar{K}$, it has been thought that $f_0(1710)$ is primarily $s\bar{s}$ dominated. In contrast, the smaller production rate of $K\bar{K}$ relative to $\pi\pi$ in $f_0(1370)$ decay leads to the conjecture that $f_0(1370)$ is governed by the non-strange light quark content.

Based on the above observations, a flavor-mixing scheme is proposed² to consider the glueball and $q\bar{q}$ mixing in the neutral scalar mesons $f_0(1710)$, $f_0(1500)$ and $f_0(1370)$. Best χ^2 fits to the measured scalar meson masses and their branching ratios of strong decays have been performed in several references by Amsler, Close and Kirk,² Close and Zhao,⁵ and He *et al.*⁶ A typical mixing matrix in this scheme is⁵

$$\begin{pmatrix} f_0(1370) \\ f_0(1500) \\ f_0(1710) \end{pmatrix} = \begin{pmatrix} -0.91 & -0.07 & 0.40 \\ -0.41 & 0.35 & -0.84 \\ 0.09 & 0.93 & 0.36 \end{pmatrix} \begin{pmatrix} |N\rangle \\ |S\rangle \\ |G\rangle \end{pmatrix}.$$

A common feature of these analyses is that, before mixing, the $s\bar{s}$ mass M_S is larger than the glueball mass M_G which, in turn, is larger than the $N(\equiv (u\bar{u} + d\bar{d})/\sqrt{2})$ mass M_N , with M_G close to 1500 MeV and $M_S - M_N$ of the order of 200 ~ 300 MeV.

Other scenarios also have been proposed. For example, based on their lattice calculations of the quenched scalar glueball mass, Lee and Weingarten^{7,8} considered a mixing scheme where $f_0(1500)$ is an almost pure $s\bar{s}$ meson and $f_0(1710)$ and $f_0(1370)$ are primarily the glueball and $u\bar{u} + d\bar{d}$ meson respectively, but with substantial mixing between the two ($\sim 25\%$ for the small component). With the effective chiral Lagrangian approach, Giacosa *et al.*⁹ performed a fit to the experimental masses and decay widths of $f_0(1710)$, $f_0(1500)$ and $f_0(1370)$ and found four

possible solutions, depending on whether the direct decay of the glueball component is considered. In spite of different opinions in the community on the identification of the scalar glueball, Particle Data Group¹⁰ tried to conclude the status as “Experimental evidence is mounting that $f_0(1500)$ has considerable affinity for glue and that the $f_0(1370)$ and $f_0(1710)$ have large $u\bar{u} + d\bar{d}$ and $s\bar{s}$ components, respectively”.

However, there are at least four serious problems with the above scenario: (i) The isovector scalar meson $a_0(1450)$ is now confirmed to be the $q\bar{q}$ meson in the lattice calculation.¹¹ As such, the degeneracy of $a_0(1450)$ and $K_0^*(1430)$, which has a strange quark, cannot be explained if M_S is larger than M_N by ~ 250 MeV. (ii) The most recent quenched lattice calculation with improved action and lattice spacings extrapolated to the continuum favors a larger scalar glueball mass close to 1700 MeV.^{12,13} (iii) If $f_0(1710)$ is dominated by the $s\bar{s}$ content, the decay $J/\psi \rightarrow \phi f_0(1710)$ is expected to have a rate larger than that of $J/\psi \rightarrow \omega f_0(1710)$. Experimentally, it is other way around: the rate for $\omega f_0(1710)$ production is about 6 times that of $J/\psi \rightarrow \phi f_0(1710)$. (iv) It is well known that the radiative decay $J/\psi \rightarrow \gamma f_0$ is an ideal place to test the glueball content of f_0 . If $f_0(1500)$ has the largest scalar glueball component, one expects the $\Gamma(J/\psi \rightarrow \gamma f_0(1500))$ decay rate to be substantially larger than that of $\Gamma(J/\psi \rightarrow \gamma f_0(1710))$. Again, experimentally, the opposite is true. Simply based on the above experimental observations, one will naively expect that $\gamma \gg \alpha > \beta$ in the wave function of $|f_0(1710)\rangle = \alpha|N\rangle + \beta|S\rangle + \gamma|G\rangle$.

In our recent work,¹⁴ we have employed two simple and robust results as the input for the mass matrix which is essentially the starting point for the mixing model between scalar mesons and the glueball. First of all, we know empirically that flavor SU(3) is an approximate symmetry in the scalar meson sector above 1 GeV. The near degeneracy of $K_0^*(1430)$, $a_0(1470)$, and $f_0(1500)$ has been observed. In the scalar charmed meson sector, $D_{s0}^*(2317)$ and $D_0^*(2308)$ have similar masses even though the former contains a strange quark. It is most likely that the same phenomenon also holds in the scalar bottom meson sector. This feature is also confirmed by the quenched lattice calculation of the masses for the isovector scalar meson a_0 and the axial-vector meson a_1 .¹¹ It is found that, when the quark mass is smaller than that of the strange, a_0 mass is almost independent of the quark mass, in contrast to those of a_1 and other hadrons that have been calculated on the lattice (see Fig. 1). This explains the fact that $K_0^*(1430)$ is basically degenerate with $a_0(1450)$ despite having one strange quark. This unusual behavior is not understood as far as we know and it serves as a challenge to the existing hadronic models. In any case, these lattice results hint at an SU(3) symmetry in the scalar meson sector. Second, an improved quenched lattice calculation of the glueball spectrum at the infinite volume and continuum limits based on much larger and finer lattices have been carried out.¹² The mass of the scalar glueball is calculated to be $m(0^{++}) = 1710 \pm 50 \pm 80$ MeV. This suggests that M_G should be close to 1700 MeV rather than 1500 MeV from the earlier lattice calculations.⁴

We shall use $|U\rangle, |D\rangle, |S\rangle$ to denote the quarkonium states $|u\bar{u}\rangle, |d\bar{d}\rangle$ and $|s\bar{s}\rangle$,

Fig. 1. Lattice calculations of a_0 and a_1 masses as a function of m_π^2 [6].

and $|G\rangle$ to denote the pure scalar glueball state. In this basis, the mass matrix reads

$$M = \begin{pmatrix} M_U & 0 & 0 & 0 \\ 0 & M_D & 0 & 0 \\ 0 & 0 & M_S & 0 \\ 0 & 0 & 0 & M_G \end{pmatrix} + \begin{pmatrix} x & x & x_s & y \\ x & x & x_s & y \\ x_s & x_s & x_{ss} & y_s \\ y & y & y_s & 0 \end{pmatrix}, \quad (1)$$

where the parameter x denotes the mixing between different $q\bar{q}$ states through quark-antiquark annihilation and y stands for the glueball-quarkonia mixing strength. Possible SU(3) breaking effects are characterized by the subscripts “s” and “ss”. As noticed in passing, lattice calculations¹¹ of the $a_0(1450)$ and $K_0^*(1430)$ masses indicate a good SU(3) symmetry for the scalar meson sector above 1 GeV. This means that M_S should be close to M_U and M_D . Also the glueball mass M_G should be close to the scalar glueball mass $1710 \pm 50 \pm 80$ MeV from the lattice QCD calculation in the pure gauge sector.¹²

We begin by considering exact SU(3) symmetry as a first approximation, namely, $M_S = M_U = M_D = M$ and $x_s = x_{ss} = x$ and $y_s = y$. In this case, two of the mass eigenstates are identified with $a_0(1450)$ and $f_0(1500)$ which are degenerate with the mass M . Taking M to be the experimental mass of 1474 ± 19 MeV,¹ it is a good approximation for the mass of $f_0(1500)$ at 1507 ± 5 MeV.¹ Thus, in the limit of exact SU(3) symmetry, $f_0(1500)$ is the SU(3) isosinglet octet state $|f_{\text{octet}}\rangle$ and is degenerate with $a_0(1450)$. In the absence of glueball-quarkonium mixing, i.e. $y = 0$, $f_0(1370)$ becomes a pure SU(3) singlet $|f_{\text{singlet}}\rangle$ and $f_0(1710)$ the pure glueball $|G\rangle$. The $f_0(1370)$ mass is given by $m_{f_0(1370)} = M + 3x$. Taking the experimental $f_0(1370)$ mass to be 1370 MeV, x is found to be -33 MeV. When the glueball-quarkonium mixing y is turned on, there will be some mixing between the glueball and the SU(3)-singlet $q\bar{q}$. If y has the same magnitude as x , the mass shift of $f_0(1370)$ and $f_0(1710)$ due to mixing is only of order 10 MeV, a feature confirmed by the lattice calculation.⁸

As discussed before, SU(3) symmetry leads naturally to the near degeneracy of $a_0(1450)$, $K_0^*(1430)$ and $f_0(1500)$. However, in order to accommodate the observed branching ratios of strong decays, SU(3) symmetry must be broken to certain degree in the mass matrix and/or in the decay amplitudes. One also needs $M_S > M_U = M_D$

in order to lift the degeneracy of $a_0(1450)$ and $f_0(1500)$. Since the SU(3) breaking effect is expected to be weak, they will be treated perturbatively.

If $f_0(1710)$ is primarily a pseudoscalar glueball, it is naively expected that $\Gamma(G \rightarrow \pi\pi)/\Gamma(G \rightarrow K\bar{K}) \approx 0.9$ after phase space correction due to the flavor independent coupling of G to PP . However, experimentally there is a relatively large suppression of $\pi\pi$ production relative to $K\bar{K}$ in $f_0(1710)$ decay. To explain the large disparity between $\pi\pi$ and $K\bar{K}$ production in scalar glueball decays, Chanowitz¹⁵ advocated that a pure scalar glueball cannot decay into quark-antiquark in the chiral limit, i.e. $A(G \rightarrow q\bar{q}) \propto m_q$. Since the current strange quark mass is an order of magnitude larger than m_u and m_d , decay to $K\bar{K}$ is largely favored over $\pi\pi$. Furthermore, it has been pointed out that chiral suppression will manifest itself at the hadron level.¹⁶ To this end, it has been suggested¹⁶ that m_q should be interpreted as the scale of chiral symmetry breaking since chiral symmetry is broken not only by finite quark masses but is also broken spontaneously. Consequently, chiral suppression for the ratio $\Gamma(G \rightarrow \pi\pi)/\Gamma(G \rightarrow K\bar{K})$ is not so strong as the current quark mass ratio m_u/m_s .

Guided by the lattice calculations for chiral suppression in $G \rightarrow PP$,¹⁷ we have performed a best χ^2 fit to the measured masses and branching ratios. The mixing matrix obtained in our model has the form:

$$\begin{pmatrix} f_0(1370) \\ f_0(1500) \\ f_0(1710) \end{pmatrix} = \begin{pmatrix} 0.78 & 0.51 & -0.36 \\ -0.54 & 0.84 & 0.03 \\ 0.32 & 0.18 & 0.93 \end{pmatrix} \begin{pmatrix} |N\rangle \\ |S\rangle \\ |G\rangle \end{pmatrix}. \quad (2)$$

It is evident that $f_0(1710)$ is composed primarily of the scalar glueball, $f_0(1500)$ is close to an SU(3) octet, and $f_0(1370)$ consists of an approximate SU(3) singlet with some glueball component ($\sim 10\%$). Unlike $f_0(1370)$, the glueball content of $f_0(1500)$ is very tiny because an SU(3) octet does not mix with the scalar glueball. Because the $n\bar{n}$ content is more copious than $s\bar{s}$ in $f_0(1710)$, it is natural that $J/\psi \rightarrow \omega f_0(1710)$ has a rate larger than $J/\psi \rightarrow \phi f_0(1710)$. Our prediction of $\Gamma(J/\psi \rightarrow \omega f_0(1710))/\Gamma(J/\psi \rightarrow \phi f_0(1710)) = 4.1$ is consistent with the observed value of 6.6 ± 2.7 . Moreover, if $f_0(1710)$ is composed mainly of the scalar glueball, it should be the most prominent scalar produced in the radiative J/ψ decay. Hence, it is expected that $\Gamma(J/\psi \rightarrow \gamma f_0(1710)) \gg \Gamma(J/\psi \rightarrow \gamma f_0(1500))$, a relation borne out by experiment. Finally, we remark that in our mixing model, the relative 2γ coupling strength is $f_0(1370) : f_0(1500) : f_0(1710) = 9.3 : 1.0 : 1.5$. Hence $f_0(1500)$ has the smallest 2γ coupling of the three states even though it has the least glue content in our model. Therefore, the fact that $f_0(1500)$ has not been seen in $\gamma\gamma$ reactions doesn't necessarily imply its glueball content.

3. Pseudoscalar glueball

In 1980, Mark II observed a resonance with a mass around 1440 MeV in the radiative J/ψ decay¹⁸ and identified it with the $E(1420)$ meson first discovered at CERN in 1963 through $p\bar{p}$ interactions.¹⁹ It was then realized that the new state observed

by Mark II was not $E(1420)$ and was subsequently named $\iota(1440)$ by Mark II and Crystal Ball Collaborations.²⁰ Shortly after the Mark II experiment, $\iota(1440)$ now known as $\eta(1405)$ was proposed to be a leading candidate for the pseudoscalar glueball. (For an excellent review of the E and ι mesons, see.²¹) Indeed $\eta(1405)$ behaves like a glueball in its productions and decays because it has a large production rate in the radiative J/ψ decay and is not seen in $\gamma\gamma$ reactions. Besides $\eta(1405)$, other states with masses below 2 GeV have also been proposed as the candidates, such as $\eta(1760)$ and $X(1835)$.

However, the pseudoscalar glueball interpretation for $\eta(1405)$ is not favored by most of the theoretical calculations. For example, quenched lattice gauge calculations predict the mass of the 0^{-+} state to be above 2 GeV in⁴ and around 2.6 GeV in.^{12,22} It is not favored by the sum-rule analysis with predictions higher than 1.8 GeV^{23,24} either. Hence, we are encountering an embarrassing situation that although experimentally $\eta(1405)$ is a favored candidate for the pseudoscalar glueball, theorists seem to prefer to have a 0^{-+} state heavier than the scalar glueball. The motivation of our recent work²⁵ is to see if we can learn something about the glueball mass by studying the $\eta - \eta' - G$ mixing.

The $\eta - \eta'$ mixing has been well studied by Feldmann, Kroll and Stech.²⁶ We extend the FKS formalism to include the pseudoscalar glueball G . In the FKS scheme, the conventional singlet-octet basis and the quark-flavor basis have been proposed. For the latter, the $q\bar{q} \equiv (u\bar{u} + d\bar{d})/\sqrt{2}$ and $s\bar{s}$ flavor states, labeled by the η_q and η_s mesons, respectively, are defined. The physical states η , η' and G are related to the octet, singlet, and unmixed glueball states η_8 , η_1 and g , respectively, through the combination of rotations

$$\begin{pmatrix} |\eta\rangle \\ |\eta'\rangle \\ |G\rangle \end{pmatrix} = \begin{pmatrix} \cos\phi + \sqrt{2/3}\sin\theta\Delta_G & -\sin\phi + \sqrt{1/3}\sin\theta\Delta_G & -\sin\theta\sin\phi_G \\ \sin\phi - \sqrt{2/3}\sin\theta\Delta_G & \cos\phi - \sqrt{1/3}\cos\theta\Delta_G & \cos\theta\sin\phi_G \\ -\sqrt{2/3}\sin\phi_G & -\sqrt{1/3}\sin\phi_G & \cos\phi_G \end{pmatrix} \begin{pmatrix} |\eta_8\rangle \\ |\eta_1\rangle \\ |g\rangle \end{pmatrix} \\ \equiv U(\phi, \phi_G) \begin{pmatrix} |\eta_8\rangle \\ |\eta_1\rangle \\ |g\rangle \end{pmatrix}, \quad (3)$$

where θ is the $\eta - \eta'$ mixing angle in the octet-singlet basis, $\phi = \theta + 54.7^\circ$, $\Delta_G = 1 - \cos\phi_G$ and ϕ_G is the mixing angle between G and η_1 ; that is, we have assumed that η_8 does not mix with the glueball.

We proceed to define decay constants for the physical and flavor states

$$\begin{aligned} \langle 0 | \bar{q}\gamma^\mu\gamma_5 q | \eta_q(P) \rangle &= -\frac{i}{\sqrt{2}} f_q P^\mu, \quad \langle 0 | \bar{q}\gamma^\mu\gamma_5 q | \eta_s(P), g(P) \rangle = -\frac{i}{\sqrt{2}} f_{s,g}^q P^\mu, \\ \langle 0 | \bar{s}\gamma^\mu\gamma_5 s | \eta_s(P) \rangle &= -i f_s P^\mu, \quad \langle 0 | \bar{s}\gamma^\mu\gamma_5 s | \eta_q(P), g(P) \rangle = -i f_{q,g}^s P^\mu. \end{aligned} \quad (4)$$

The decay constants associated with the η meson, η' meson, and the physical glueball are related to those associated with the η_q , η_s , and g states via the same mixing

matrix

$$\begin{pmatrix} f_\eta^q & f_\eta^s \\ f_{\eta'}^q & f_{\eta'}^s \\ f_G^q & f_G^s \end{pmatrix} = U(\phi, \phi_G) \begin{pmatrix} f_q & f_q^s \\ f_s^q & f_s^s \\ f_g^q & f_g^s \end{pmatrix}. \quad (5)$$

Sandwiching the equations of motion for the anomalous Ward identity

$$\partial_\mu (\bar{q} \gamma^\mu \gamma_5 q) = 2im_q \bar{q} \gamma_5 q + \frac{\alpha_s}{4\pi} G_{\mu\nu} \tilde{G}^{\mu\nu}, \quad (6)$$

between vacuum and $|\eta\rangle$, $|\eta'\rangle$ and $|G\rangle$, we derive

$$\begin{pmatrix} m_{qq}^2 + (\sqrt{2}/f_q) \langle 0|q|\eta_q \rangle & m_{sq}^2 + (1/f_s) \langle 0|q|\eta_q \rangle & 0 \\ m_{qs}^2 + (\sqrt{2}/f_q) \langle 0|q|\eta_s \rangle & m_{ss}^2 + (1/f_s) \langle 0|q|\eta_s \rangle & 0 \\ m_{qg}^2 + (\sqrt{2}/f_q) \langle 0|q|g \rangle & m_{sg}^2 + (1/f_s) \langle 0|q|g \rangle & 0 \end{pmatrix} = U^\dagger(\phi, \phi_G) M^2 U(\phi, \phi_G) \tilde{J}, \quad (7)$$

where $q = \alpha_s G \tilde{G} / (4\pi)$ and

$$M^2 = \begin{pmatrix} m_\eta^2 & 0 & 0 \\ 0 & m_{\eta'}^2 & 0 \\ 0 & 0 & m_G^2 \end{pmatrix}, \quad \tilde{J} = \begin{pmatrix} 1 & f_q^s/f_s & 0 \\ f_s^q/f_q & 1 & 0 \\ f_g^q/f_q & f_g^s/f_s & 0 \end{pmatrix}, \quad (8)$$

with the abbreviation

$$m_{qq,qs,qg}^2 \equiv \frac{\sqrt{2}}{f_q} \langle 0|m_u \bar{u} i \gamma_5 u + m_d \bar{d} i \gamma_5 d | \eta_q, \eta_s, g \rangle, m_{sq,ss,sg}^2 \equiv \frac{2}{f_s} \langle 0|m_s \bar{s} i \gamma_5 s | \eta_q, \eta_s, g \rangle.$$

Now we have six equations for many unknowns. Hence we have to rely on the large N_c counting rules²⁷

$$\begin{aligned} f_{q,s} &\sim O(\sqrt{N_c}), & f_g^{q,s} &\sim O(1), & f_q^s &\sim f_s^q \sim O(1/\sqrt{N_c}), \\ m_G &\sim O(1), & m_{\eta_s}^2 &\sim O(1), & m_{\eta_1}^2 &\sim O(1) + O(1/N_c), \\ m_{qq}^2 &\sim O(1), & m_{ss}^2 &\sim O(1), & \phi_G &\sim O(1/\sqrt{N_c}), \\ m_{qg}^2 &\sim m_{sg}^2 \sim O(1/\sqrt{N_c}), & m_{qs}^2 &\sim m_{sq}^2 \sim O(1/N_c), \\ \langle 0|q|g \rangle &\sim O(1), & \langle 0|q|\eta_q \rangle &\sim \langle 0|q|\eta_s \rangle \sim O(1/\sqrt{N_c}), \end{aligned} \quad (9)$$

to solve the equations step by step.

To the leading order of $1/N_c$ expansion, we shall keep the decay constants f_q and f_s and neglect $f_g^{q,s}$, f_q^s and f_s^q as they are suppressed by $1/\sqrt{N_c}$ and $1/N_c$, respectively. Likewise, we can just retain the diagonal mass terms $m_{qq}^2 \approx m_\pi^2$, $m_{ss}^2 \approx 2m_K^2 - m_\pi^2$ and neglect other off-diagonal mass terms. It turns out that the ratio of the last two equations in the third row of Eq. (7) yields

$$\frac{c\theta(s\phi - \sqrt{2/3}c\theta\Delta_G)m_{\eta'}^2 - s\theta(c\phi + \sqrt{2/3}s\theta\Delta_G)^2m_\eta^2 - \sqrt{2/3}c\phi_G m_G^2}{c\theta(c\phi - \sqrt{1/3}c\theta\Delta_G)m_{\eta'}^2 + s\theta(s\phi - \sqrt{1/3}s\theta\Delta_G)^2m_\eta^2 - \sqrt{1/3}c\phi_G m_G^2} = \frac{\sqrt{2}f_s}{f_q} \quad (10)$$

where $c\phi$ ($s\phi$) is the shorthand notation for $\cos\phi$ ($\sin\phi$) and similarly for others. *This simple equation tells us that the pseudoscalar glueball mass m_G can be determined provided that the mixing angle ϕ_G and the ratio f_s/f_q are known.* Note that

Table 1. Solutions for the input of $\langle 0|q|\eta_q\rangle = 0.050 \text{ GeV}^3$ and f_s being fixed to trade for m_{sg}^2 as a free parameter. The upper (lower) table is for $\phi_G = 22^\circ$ ($\phi_G = 12^\circ$), $r \equiv f_g^s/f_s$ and $R \equiv f_q^s/f_s$.

$1.30f_\pi$	0.24	-0.005	0.018	1.16	0.028	0.045

the ϕ_G dependence appears at order of $\Delta_G \approx \phi_G^2$ for small ϕ_G . So the solution for m_G is stable against the most uncertain input ϕ_G .

The mixing angles ϕ and ϕ_G have been measured recently from the $\phi \rightarrow \gamma\eta, \gamma\eta'$ decays by KLOE.²⁸ Using the decay constants $f_q = (1 \pm 0.01)f_\pi$ and $f_s = (1.4 \pm 0.014)f_\pi$ as inputs,²⁹ KLOE obtained the angles $\phi = (39.7 \pm 0.7)^\circ$ and $\phi_G = (22 \pm 3)^\circ$ inferred from the relevant data. In³⁰ the data of $P \rightarrow \gamma V$ and $V \rightarrow \gamma P$ were first considered and the fit gave the outcomes $\phi = (41.4 \pm 1.3)^\circ$ and $\phi_G = (12 \pm 13)^\circ$. Without precise inputs of f_q and f_s it is not unexpected to get a wide range for ϕ_G . Since ϕ_G has a wide range, the results $f_q = (1.05 \pm 0.03)f_\pi$ and $f_s = (1.57 \pm 0.28)f_\pi$ also have larger errors. Using the central values of f_s/f_q and ϕ_G from^{28,30} as inputs, we derive the pseudoscalar glueball mass from Eq. (10) to be

$$m_G = (1.4 \pm 0.1) \text{ GeV}. \quad (11)$$

The proximity of the predicted m_G to the mass of $\eta(1405)$ and other properties of $\eta(1405)$ make it a very strong candidate for the pseudoscalar glueball.

Our next task is to check the stability and robustness of our prediction when higher order effects in $1/N_c$ are included. We first turn on the decay constants $f_g^{q,s}$ and f_q^s, f_s^q . Assuming flavor-independent couplings between the glueball g and the pseudoscalar $u\bar{u}, d\bar{d}$ and $s\bar{s}$ states, we then have the relations

$$f_g^q = \sqrt{2}f_g^s, \quad f_s^q = f_q^s. \quad (12)$$

It turns out that the above simple formula Eq. (10) still holds even after keeping the OZI-correcting decay constants, as long as they obey Eq. (12).

Finally we turn on the mass term m_{sg}^2 and neglect m_{qg}^2, m_{qs}^2 and m_{sq}^2 . It is justified to do so because m_{qg}^2 is proportional to the light u/d quark mass, while the last two mass terms are $1/\sqrt{N_c}$ suppressed relative to m_{sg}^2 . To explore the impact of m_{sg}^2 on our solutions, we add f_s as an input so that m_{sg}^2 can be introduced as an unknown. The results for the various inputs of $f_s = (1.24-1.30)f_\pi$, $\phi_G = 22^\circ$ and 12° , and $\langle 0|q|\eta_q\rangle = 0.050 \text{ GeV}^3$ are listed in Table 1. We see that m_{sg}^2 and m_G do depend on f_s sensitively. In some cases, we have m_G as large as 1.84 GeV and

2.15 GeV, for which m_{sg}^2 are negative and large. We cannot discard these solutions of m_{sg}^2 *a priori*, but they are not favored due to their negative values. This issue can be sorted out, when lattice calculations of m_{sg}^2 with dynamical fermions are available. Therefore, if excluding the solutions with large and negative m_{sg}^2 , the range (1.4 ± 0.1) GeV of the pseudoscalar glueball mass obtained in Eq. (11) will be more or less respected.

One may feel rather uncomfortable with our solution for m_G as both lattice QCD and QCD sum rules indicate a pseudoscalar glueball heavier than the scalar one. The point is that lattice calculations so far were performed under the quenched approximation without the fermion determinants. It is believed that dynamical fermions will have a significant effect in the pseudoscalar channel, because they raise the singlet would-be-Goldstone boson mass from that of the pion to η and η' . Indeed, it has been argued that the pseudoscalar glueball mass in full QCD is substantially lower than that in the quenched approximation.²⁴ In view of the fact that the topological susceptibility is large (of order 10^{-3} GeV^4) in the quenched approximation, and yet is of order 10^{-5} GeV^4 in full QCD and zero in the chiral limit, it is conceivable that full QCD has a large effect on the pseudoscalar glueball as it does on η and η' .

According to our analysis, the $\eta(1405) \rightarrow \gamma\gamma$ decay width is 0.6-3 keV, and the leptonic decays $\eta(1405) \rightarrow \ell^+\ell^-$ are very small.²⁵ Both predictions can be confronted with future experiments. There may not exist a unique feature which tells a glueball apart from a quark-antiquark state. We need to combine information from J/ψ radiative decays, hadronic decays, as well as $\gamma\gamma$ and leptonic decays as advocated in.³¹

4. Conclusions

We have employed two simple and robust results to constrain the mixing matrix of the isosinglet scalar mesons $f_0(1710)$, $f_0(1500)$, $f_0(1370)$: (i) empiric SU(3) symmetry in the scalar sector above 1 GeV, and (ii) the scalar glueball mass at 1710 MeV in the quenched approximation. In the SU(3) symmetry limit, $f_0(1500)$ becomes a pure SU(3) octet and is degenerate with $a_0(1450)$, while $f_0(1370)$ is mainly an SU(3) singlet with a slight mixing with the scalar glueball which is the primary component of $f_0(1710)$. These features remain essentially unchanged even when SU(3) breaking is taken into account.

From the analysis of the $\eta - \eta' - G$ mixing together with the inputs from the recent KLOE experiment, we find a solution for the pseudoscalar glueball mass around (1.4 ± 0.1) GeV, suggesting that $\eta(1405)$ is indeed a leading candidate for the pseudoscalar glueball. It is thus urgent to have a full QCD lattice calculation of pseudoscalar glueball masses.

Acknowledgments

I'm very grateful to Chun-Khiang Chua, Hsiang-nan Li and Keh-Fei Liu for the fruitful collaboration on glueballs and to K K Phua for organizing this wonderful conference.
